

Determining relations between core dimensions of collaboration quality

A multidimensional scaling approach

Abstract—Computer Supported Collaborative Learning (CSCL) constitutes one of the most extensively developed paradigms of research and practice in intelligent networking and collaborative systems technology. Interdisciplinarity in the research field involves the application of several methodological approaches towards analysis of CSCL that range from deep-level qualitative analyses of small interaction-rich episodes of collaboration, to quantitative measures of suitably categorized events of interaction that are used as indicators of the success of collaboration in some of its facets [1]. This article adopts an alternative approach to CSCL analysis that aims at taking advantage of some desired properties of each of these diverse methodological trends, involving the use of a rating scheme for the assessment of collaboration quality [2][3]. After defining a set of dimensions that cover the most important aspects of collaboration, it employs appropriately trained human agents to assign ratings of collaboration quality to each dimension, basing their assessments on substantial aspects of collaboration which are not easily formalisable. The activities studied here regard 228 collaborating dyads, working synchronously on a computer science problem-solving task with the use of the Synergo tool [4]. Based on this large dataset, relations between dimensions of collaboration quality are unraveled on empirical grounds, based on the ratings of collaboration quality that were elaborated statistically using the multidimensional scaling technique [5,6,7,8,9,10,11]. Results obtained are in accordance with the initial design of the rating scheme used, and further particularize the relations between the dimensions it defines.

Keywords—computer supported collaborative learning; multidimensional scaling; rating scheme; synchronous collaborative problem-solving

I. INTRODUCTION

Computer Supported Collaborative Learning (CSCL) constitutes one of the most extensively developed paradigms of research and practice in intelligent networking and collaborative systems technology. Under specific conditions, collaborative interactions can trigger collaborative knowledge building [12] that is beneficial for learners participating in collaborative processes.

Apart from the study of the conditions that can lead to fruitful CSCL processes, and the “learning gains” that students may obtain, analysis of collaborative interactions per se constitutes one of the core aspects of the study of

CSCL [13]. Interdisciplinarity in the research field involves the application of several methodological approaches towards analysis of CSCL that range from deep-level qualitative analyses of small interaction-rich episodes of collaboration, to quantitative measures of suitably categorized events of interaction that are used as indicators of the success of collaboration in some of its facets [1].

Whereas the latter paradigm of CSCL analysis offers possibilities for practical facilities such as quick or even automated assessments of collaboration as in [4, 14], it is many times based on surface aspects of collaboration. On the other hand, approaches that fall on the former paradigm, such as [15,16], may be rightly considered the most suitable for in-depth CSCL analysis, they are, however, arduous and time-consuming when dealing with large-scale studies involving extended datasets. This article adopts an alternative approach to CSCL analysis that aims at taking advantage of some desired properties of each of these diverse methodological trends. It involves the use of a rating scheme for the assessment of collaboration quality [2]. After defining a set of dimensions that cover the most important aspects of collaboration, it employs appropriately trained human agents to assign ratings of collaboration quality to each dimension, basing their assessments on substantial aspects of collaboration which are not easily formalisable. Still, the outcome of the evaluation process is provided in quantitative form, suitable for the statistical manipulation.

The activities studied here regard 228 collaborating dyads, working synchronously on a computer science problem-solving task with the use of the Synergo tool [4]. Based on this large dataset, relations between dimensions of collaboration quality are determined on empirical grounds, based on the ratings of collaboration quality applied for each dimension in each collaborative session. The technique selected, which allows the systematic view of these associations in statistical means, is multidimensional scaling [5,6,7,8,9,10,11], using dimensions of collaboration quality as the unit of analysis. That way, associations between core aspects of collaboration are represented in a three-dimensional space, with distances between dimensions denoting their dissimilarities. The results obtained are in accordance with the initial design of the rating scheme used, and further particularize the relations between its dimensions. General conclusions and further steps made

possible by current findings are discussed in the last section of this paper.

II. COLLABORATIVE SETTING

Collaborative activities studied in this article involved about 350 computer science students at the department of Electrical and Computer Engineering of the University of Patras, Greece, engaged in jointly building the diagrammatic representation of an algorithm as an assignment of a two-hour laboratory session that was part of the first-year of studies course “Introduction of Computers and Algorithms”. These activities took place in a single laboratory room, equipped with one computer per student. Students interacted through Synergo [4], communicating via an integrated chat tool, and jointly designing a flow-chart representation of an algorithm in Synergo’s shared whiteboard. A capture of a user’s screen while collaborating with Synergo is shown in Figure 1. Synergo provides libraries of objects supporting the notation of several diagrammatic models. Collaborative sessions lasted from 45 to 75 minutes and students worked in dyads. They were free to use their own resources such as textbooks or the web and were permitted to ask questions to a teacher, who restricted her feedback to technical or other minor aspects. In order to motivate students to work on the exercises collaboratively, they were informed that the grade they would get for the particular lab session (all the laboratory exercises determined 30% of their final course grade) would be formed in equal parts by determining the quality of their collaboration and the completeness and correctness of their joint solution. Dyads were arranged in space in a way that it was impossible for the students to use any other means of communication apart from these provided by Synergo.

The problem domain of the task was basic algorithms in computer science. Students were asked to solve elementary algorithm exercises that are widely used for training basic algorithmic skills. For example, a basic piece of knowledge in algorithms is the concept of the variable [17], which should be discriminated from the understanding of the variable that students may have obtained in mathematics. Another major learning object was also the proper handling of algorithmic structures, such as the loop structure [18]. Participants were asked to solve specific algorithm problems requiring the use of these concepts by developing flowchart diagrams, a widely used modelling practice that provides a semiotic space for the design of algorithms [19]. The task given to students can be considered an “intellective task” with a “demonstrably correct solution” [20]. The correctness of the solution is concretely defined, based on the notation of algorithms used. There are, of course, alternative ways to develop parts of the solution that are equally acceptable and correct, however, in each case, arguments on correctness and the pros and cons of each alternative can be based on solid criteria. All students were taught the knowledge demanded in order to handle the task sufficiently in university lectures before the lab sessions took place, although some of them may have been already familiar with the task domain from secondary education curricula.

III. DETERMINING DIMENSIONS OF COLLABORATION QUALITY

The first step of analysis for the current study dealt with the definition of a conceptual framework of collaboration that is multidimensional, i.e. it defines several dimensions that cover core aspects of collaboration, and, on a second level, can be operationalised into a tool suitable for making assessments of specific instances of collaborative processes. An extended literature search [21] led to the adoption of the work by Meier, Spada, and Rummel [3], who proposed a multidimensional conceptual framework suitable for the assessment of collaboration quality in synchronous interdisciplinary problem-solving through videoconferencing systems, in a study that significantly influenced the work presented here.

The conceptual framework defined several dimensions of collaboration quality, further categorized into broader aspects of collaboration. The first broader aspect defined regards communication. On a first level, one dimension of collaboration deals with the need for the establishment of *common ground* of mutually shared concepts, assumptions and expectations [22] between the participants. Common ground can be achieved and sustained if both partners (in the case of a dyad) work towards *grounding* their conversations on a moment-to-moment basis [23]. Good practices in this dimension regard extra effort from the participants in order e.g. for a sender of an utterance to try to make her contribution understandable to their peer, or, for a receiver, to try to indicate understanding of what has been uttered. On a more elementary level, the framework covers apart from the content of communication, the process of communicating as well. Practices of participants such as ensuring mutual attention [22], and the proper management of the turn-taking mechanism are considered appropriate for the success of a collaborative process.

The second broader aspect of the framework is generally described as *information processing*. It covers collaborative activity that is tightly related to the task. On a first level,

what is of major importance for successful collaboration in this aspect is that participants exchange and process information based on their complementary knowledge, so that they can build a shared knowledge base. In social psychology, the terms of information pooling and transactive memory [24] play a crucial role in describing such processes. From a collaborative learning research standpoint, similar processes are studied under the term of knowledge acquisition. Knowledge acquisition can be achieved either by externalization of a participant's personal knowledge, or by its elicitation by their peer by asking for explanations [25]. On another level, after the pooling of information, collaborators have to reach a common decision on the best solution to the problem. In order to achieve that, collaborators have to evaluate the information exchanged, by stating arguments for and against the options at hand, and critically discussing different perspectives [26].

Another important facet of collaboration regards the coordination of participants on a broader level than the one mentioned before: on the task rather than the communicational level. It deals with practices of efficient structuring of the problem-solving process that involve issues such as the intelligent division into sub-tasks between participants (e.g. the optimal handling of interdependencies that may occur when subtasks build up on each other, or conflicts when group members need to access the same shared resources [3]), the efficient management of the time resources available, and the proper handling of coordination demands imposed by the mediating tool's technicalities.

In addition to communication, information processing, and task coordination aspects, social aspects of collaboration are also given due attention by the conceptual framework. Under the frame of the *managing interpersonal relationships* aspect, the framework covers issues such as interpersonal support, helpfulness and friendliness that can be constructive for successful collaboration. Such desired practices can be reflected in the symmetry of the relationship, the extent of supportive communication and the way the conflicts are handled [27].

Finally, the last category covered by Meier, Spada, and Rummel's conceptual framework [3] deals with motivational aspects of collaboration. Orientation and dedication to the task on behalf of both participants rather than on task-irrelevant issues is considered to be a prerequisite of successful collaboration.

The conceptual framework described above was motivated and led to the definition of a rating scheme suitable for applying assessments of collaboration quality in all of its core dimensions. The rationale of this evaluation approach is described in more detail in the subsequent section.

IV. THE RATING APPROACH

A. Rating scheme

The framework described in the previous section was operationalised through a rating scheme that was used as for assessing collaboration quality in its core dimensions. As an

analysis tool, the rating scheme combines desirable properties of qualitative and quantitative techniques. Observed behavior can be compared to a predefined standard of exemplary collaboration that has been formed based on established CSCL theory and thorough empirical analyses of typical collaborative sessions. This can then lead to quantitative judgements of the quality of collaboration. The main advantage of the rating approach compared to common quantitative analysis is that it offers quantitative results that measure subtle aspects of collaboration (mainly being the object of study of in-depth qualitative analyses), rather than gross metrics that are usually based on quantities of events of users' interactions with the mediating tools. Simultaneously, in contrast to the approach adopted in this work, common qualitative approaches that demand in-depth analysis of collaboration usually can not be extended to more than a few rich episodes of collaboration, whereas issues of reliability and generalisability are more difficult to overcome in such cases.

Concerning the practical efficiency of analysis, rating processes are time-effective, since assessment using the rating scheme is relatively quick, provided that raters have been sufficiently trained. Another important characteristic of the rating scheme analysis tool, is that it is multi-dimensional, i.e. it is used for assessing several dimensions of collaboration distinctly. In that way, the results of rating can be used for indicating which dimensions of collaboration are the most problematic and provide e.g. the opportunity for giving adaptive feedback and specialized instructions.

Due to significant differences between the setting that lead to the definition of Meier, Spada, and Rummel's rating scheme and the current setting, a laborious process of generalising and adapting the initial conceptual framework to the current setting was followed (reported in detail in [28]). The adaptation of the rating scheme was done in two main phases: the first resulted in an adapted definition of the rating scheme's dimensions, and the second served to fine-tune the rating instructions. In the first phase of adaptation a bottom-up approach, which involved identification of "best practice" examples in the sample data, was combined with a top-down process, during which the definitions of all original dimensions were reformulated taking into account constraints and affordances characterizing the specific collaboration setting. In the second phase of adaptation, the dimensions' definitions were fine-tuned and illustrated with more detail, grounding each dimension's theoretical concepts in specific examples of collaboration practice from the data pool of the first round of adaptation [28]. The resultant rating scheme specifies seven core dimensions of collaboration quality presented in Table I.

The structure of the new scheme is in accordance with the rationale of the initial one, while definitions of dimensions do not only aim at fitting the current setting, but at being more generalisable as well.

TABLE I. THE ADAPTED RATING SCHEME

General aspect of collaboration	Dimension of collaboration
Communication	Collaboration flow
	Sustaining mutual understanding
Joint information processing	Knowledge exchange
	Argumentation
Coordination	Structuring the Problem Solving Process
Interpersonal relationship	Cooperative orientation
Motivation	Individual task orientation

B. Rating process

All dimensions were rated on the level of the collaborating dyad with the exception of individual task orientation which was rated for each participant separately. Like in the initial approach by Meier, Spada, and Rummel [3], the ratings were applied in the scale from -2 to 2 with a step of 1 unit. One rating was assigned for each dimension of collaboration quality per collaborative session. A handbook was also developed in order to assist raters providing a rich source of detailed definitions of all dimensions, along with rating instructions and illustrative examples of episodes from the dataset. The rating process was based on video-like reproductions of the activities facilitated by the Synergo's playback tool [28].

The rating procedure was carried out in two main phases. The first one, reported in detail in [28], consisted of 101 dyads which were rated for each dimension by two raters with prior experience with the current setting, after an extended pilot phase of training. Inter-rater reliability scores were very good. The second phase, which was deemed necessary in order to extend the population of collaborative sessions, consisted of additional 149 dyads, for which the design and setting of the labs was identical with the one used in the first phase, varying only in minor aspects of task details, and being thus appropriate for integrated analysis. This way, large-scale statistical elaborations from several points of view, such as the one presented later in this article, became possible. In the second phase, the ratings were applied by the same raters as in the first one and inter-rater reliability was examined for this phase as well.

C. Reliability of ratings

Results of inter-rater reliability of the second rating procedure for each dimension of the scheme are illustrated in Table 2. For the seventh dimension, the reliability scores for the average rating between the two students and their absolute difference are provided. The table contains also reliability scores for the average of the six first dimensions of the scheme.

Reliability scores are good in reference to all empirical rules of thumb found in the literature [29,30,31,32].

TABLE II. INTER-RATER RELIABILITY SCORES FOR EACH DIMENSION

General aspect of collaboration	Dimension of collaboration	ICC	ICC (adj. = r)	Cronb. α	Spe ar. ρ
Communication	Coll. flow	.76	.77	.87	.74
	Sust. mut. underst.	.79	.82	.89	.80
Joint information processing	Knowl. exchange	.81	.81	.89	.74
	Argumentation	.77	.77	.87	.75
Coordination	Struct. the Probl. Solv.Proc.	.70	.69	.82	.71
Interpersonal relationship	Coop. orient.	.82	.83	.90	.79
Motivation	Ind. task orient. (mean)	.71	.75	.84	.59
	Ind. task orient. (diff.)	.87	.87	.93	.61
-	Average 6 dims	.89	.89	.94	.86

V. RELATIONS BETWEEN DIMENSIONS OF COLLABORATION QUALITY

To some extent, relations between dimensions of collaboration quality can be roughly conceived from the definition of the conceptual framework and the rating scheme. Nevertheless, the extended dataset gathered offers the opportunity to validate such top-down assumptions empirically, by applying suitable statistical manipulations on the data. Moreover, the exact relations between dimensions can be detected based on the ratings applying in 228 cases.

A. Multidimensional scaling of dimensions of collaboration quality

A systematic way to obtain an overall view on the associations among collaborative dimensions and empirically evaluate the use of the scheme regards the conduction of a MultiDimensional Scaling (MDS) analysis based on the bivariate correlations between them [5,6,7,8,9,10,11]. MDS analysis is based on measures of similarities between variable pairs and no assumptions are presupposed on the distribution of the values which the variables take, the types of their similarity relations, or the way the similarity measures are obtained.

In the specific case of this study, the unit of analysis of the technique is the collaborative dimension as it is defined by the rating scheme. The technique provides insightful two-dimensional diagrams representing the position of collaborative dimensions in such a way that dimensions correlated tightly are placed closer to each other in space than dimensions that do not relate that much. For the current application of the technique, disparities between correlations are represented with a spatial Euclidian distance.

The MDS algorithm used was SMACOF (Scaling by MAjorizing a CONVex Function) [33] as it is implemented by

XLSTAT [34]. This iterative algorithm aims at minimizing the normalized differences between a similarity matrix given as an input (converted to a dissimilarity matrix) and the corresponding distance matrix that is represented as the outcome of the process.

B. Results and internal validation of the MDS algorithm

The results of the application of the technique are depicted in Figure 2 (using Kendall's τ scores for the calculation of correlations) and Figure 3 (using Spearman's ρ for the calculation of correlations). The two diagrams are very similar and lead to the same interpretations.

Figure 2. Multidimensional scaling with the 6 collaborative dimensions using a similarity matrix based on Kendall's correlations

Figure 3. Multidimensional scaling with the 6 collaborative dimensions using a similarity matrix based on Spearman's ρ correlations

The following Figures 4 and 5 illustrate the Shepard diagrams of the application of the technique using Kendall's τ and Spearman's ρ values respectively.

Figure 4. Shepard diagrams of MDS algorithm using Kendall's τ correlations

Figure 5. Shepard diagrams of MDS algorithm using Spearman's ρ correlations

The Shepard diagram [35] is a scatter-plot that depicts the configured distances for the two-dimensional model in relation to the observed distances used as input [36]. The filled circles in the diagram represent the Euclidean distances presented by the MDS algorithm, whereas the empty circles represent the distances calculated by the monotonic regression function of the algorithm [33]. The latter's slope is represented by the lines of Figures 4 and 5. The square root of the normalised sum of squared residuals between the filled circles and the straight line is measured by Kruskal's stress [37], which provides an estimation of the goodness-of-fit of the results. Kruskal's stress for the first application of the algorithm was measured at the acceptable level [37, 10] of 0.062 for the concluding 28th iteration of the algorithm, whereas for the second application it took a similar value (0.065) at the 30th iteration. In both cases, the convergence criterion for the final version of the model stated that the stress value of the final iteration should be improved from the previous iteration by less than 0.00001.

C. Interpretation of the MDS results

As is evident from Figures 2 and 3, dimensions covering different aspects of collaboration quality cover four different parts of the two-dimensional space (the dimension belonging to the motivational aspect is not contained in the diagram since it is rated differently than other dimensions). Dimensions covering the same aspect of collaboration (denoted by the same color in the diagram) stand close to each other. Regarding the interpretation of Figure 2, the coordinates of each dimension do not denote the quality of collaboration in a quantitative manner; they are used for the representation of its distance from other dimensions. Therefore, the range of each axis should be thought of as representing aspects of collaboration that differentiate dimensions on the way they reflect different facets of this specific axis. The rationale followed in order to reach meaningful interpretations is described below.

Higher-order dimensions are reported with higher absolute values on the vertical axis, while lower level ones have higher absolute values on the horizontal axis (cooperative orientation, which is placed near the zero-point does not straightforwardly relate to any of these axes). Thereby, the vertical axis can be considered to stand for high-level collaboration aspects and the horizontal axis to stand for lower-level collaboration aspects.

Concerning the horizontal axis, the two communicational dimensions are placed on the right of the diagram, taking positive values, whereas the two information processing dimensions are placed on the left, taking negative values. Thus, from left to right, the horizontal axis can be considered to designate the range from task-related low-level facets of collaborative activity to task-unrelated facets of collaborative activity (task-related in this case refers to these aspects of collaboration that are significantly shaped by the specific task to be solved). In the case of lower level collaborative activity, task-unrelated facets mostly refer to communicational aspects. Collaboration flow takes the largest positive (and absolute) value on the axis, since it constitutes the lowest level dimension of the scheme. Sustaining mutual understanding, on the other hand, is placed closer to the 0 point and has a more noticeable Y coordinate. Among the information processing dimensions, knowledge exchange has the biggest negative value because argumentation is related more to high-level collaborative activity. Structuring the problem solving process is also placed left from the Y axis. According to the interpretation of the axes developed above, this reflects the fact that structuring the problem solving process is shaped by task-related issues in the lower level of collaboration. For example, an algorithm development problem favors practices of task coordination such as the development of different parts of the algorithm by participants in parallel (which are defined according to the task's demands), the proper placement of flow-chart objects by each student so that the two parts can be then combined, or the development of a part of the algorithm by one student while their partner is checking its correctness by assigning values to variables.

Such practices are highly task-dependent and would not be reproduced in the case of a task of a different kind.

A similar rationale applies to the vertical axis concerning higher-level collaboration; structuring the problem solving process takes the highest absolute value on the upper part of the diagram, while the two information processing dimensions lie on the negative part of the axis. So, in a similar way with the vertical axis, the horizontal one can be considered to denote from up to down the range from task-unrelated high-level facets of collaborative activity to task-related high-level facets collaborative activity. Among the two joint information processing dimensions, argumentation takes a significantly higher value than information processing, due to the fact that the former reflects higher-level facets of this aspect of collaborative activity. Structuring the problem solving process, in this axis, takes a significantly positive value. Contrary to lower level aspects that the same dimension covers, higher level aspects of structuring the problem solving process are not tight to the specific task. They mainly refer to general strategies of collaborative problem solving, such as the division of labour between participants, the evaluation of one student of the other students work, and time management concerns so that a complete solution can be delivered on time. Communicational dimensions take approximately zero values on the vertical axis, since they are related to lower level aspects of collaboration. Among the two dimensions, sustaining mutual understanding appears to have a small load to the vertical axis, due to the fact that it is, even limitedly, related more to higher level issues than collaboration flow is.

Concerning both axes, cooperative orientation is located very close to the zero point. Social aspects of collaboration that relate to cooperative orientation do not have a straightforward mapping with higher or lower task-related or non task-related facets of collaboration, even though the dimension is correlated highly with all other dimensions of the scheme, something denoted in the diagram with its central position.

In general, results obtained from the MDS algorithm are in accordance with the definition of the dimensions of the rating scheme. Distances represented by the algorithm are reasonable: a diagram of a similar rationale, applied by the researchers in a top-down manner, would probably resemble the one found empirically. Moreover, the approach offers subtler information on the exact associations between dimensions.

Concluding, it should be stated that the definition of the axes is to some extent arbitrary and their descriptions related to higher and lower-level aspects of collaboration constitute an interpretation rather than an "objective" result of the technique. The examined instance of the MDS technique could lead to the same information with the axes rotated, or their signs inversed. What would remain the same is the relative position of the dimensions (not regarding minimal differences attributed to the goodness-of-fit of the algorithm). Therefore, for the output of the algorithm presented in the figures above, the algorithm was initialized in such a way that the axes would be more interpretable.

VI. CONCLUSIONS

The work reported in the current article implemented a rating scheme based approach for the evaluation of synchronous problem-solving collaborative activities in order to gain insight into the relations between distinct dimensions of collaboration quality. The multidimensional scaling approach, which was applied in a large dataset of collaborative sessions, largely confirmed on empirical grounds the rationale of the conceptual framework of the rating tool used, as regards the relations between core dimensions of collaboration quality. Furthermore, it provided additional insight on the exact placement of each dimension of collaboration in reference to two general axes of collaborative activity.

Future research directions related to this work can follow several paths: statistical analysis reported here can be supplemented by in-depth qualitative investigations of collaborative activities, which can shed more light into the way different dimensions of collaboration are interlinked with each other in collaborative practice. Common trends that determine the placement of dimensions of collaboration close or far from each other in the MDS representation can serve as the initial point for further qualitative analysis based on interesting instances of collaboration that may reveal subtler associations between aspects of different dimensions, or recurring patterns of the simultaneous occurrence of good or bad practices in specific dimensions.

Furthermore, the current approach can be replicated using different versions of the rating scheme or applied in different settings of collaboration. Such efforts would help to indicate the extent to which current findings are indicative of the way dimensions of collaboration are associated with each other in general, or if they mostly pertain to the specific CSCL setting under study.
